Multivariate CAViaR

A More Insightful Approach to Risk Modeling Steven Moen Thursday, April 30th, 2020

Abstract

This paper builds upon previous literature for modeling value-at-risk quantiles that uses an ARMA-style approach by adding ETFs as explanatory variables that are combined into principal component vectors at the forecast origin. By combining these principal component vectors along with various transformations of lagged autoregressive response variables, similar predictive accuracy is achieved (relative to the univariate model) and a clearer interpretation is gained. In fact, this thesis proposes an algorithm to detect changepoints in the explanatory variables that could be used as a means to measure changepoints in the economy. [DELETE IF THE CHANGEPOINT ARGUMENT DOESN'T MAKE SENSE.]

Background and Introduction

When modeling financial time series, simply considering the mean and the variance is insufficient. In fact, modeling a 1% or a 5% quantile of daily returns is a way to understand what happens on the worst days and to have a clearer picture of what might happen during a downturn. Indeed, finance theory suggests that a primary reason why the S&P500, which is a market-capitalization weighted index composed of the 500-largest publicly traded companies in the United States, has earned 6.8% inflation-adjusted pre-tax return with dividend reinvestment from January 1871 through April 2020 (CITE) is because of the risk of a significant downturn. Kerry Pechter at Forbes describes it as a premium for the fact that "stocks are riskier" and "more prone to price fluctuations in the short run" compared to lower risk investments. While the long-run picture of stock returns is a bit clearer, the short-run is a huge question - an investment manager using financial leverage to magnify returns (positive or negative) that could leave them in dire straits if their investments fell rapidly, despite a sound long-run strategy.

While there are other ways to understand and measure downside risk, a commonly accepted means is using value-at-risk (VaR). The metric is understood as follows: a one-day 1% VaR of -1 million dollars for a portfolio means that the portfolio will lose at least \$1 million on the 1% worst trading days. A major advantage of VaR is that it distills a distribution of returns into one number. As such, VaR is often used in stress testing by regulatory agencies in the United States, the United Kingdom, and Europe (CITE).

Many of the approaches for modeling VaR rely on a semiparametric or a nonparametric historical simulation (ADD CITATION - BOUDOUKH). According to Robert Engle and Simone Manganelli in a 2004 paper, these methods are usually chosen for "empirical justifications rather than on sound statistical theory" (ADD CITATION - ENGLE). As such, they propose a framework called CAViaR that forecasts the VaR quantile directly using a conditional autoregressive quantile specification. This approach builds upon the statistical literature that extends linear quantile models to settings amenable to financial modeling, such as with heteroskedastic and nonstationary error distributions (ADD CITATION - KOENKER, PORTNOY).

Methods Used

A common problem in statistical analysis occurs when a training sample is significantly different than that of the test sample. Initial motivations for this paper involved analyzing two stocks - Amazon (ticker: AMZN) and Proctor & Gamble (ticker: PG) and their performance during the great recession. A relevant question of a financial institution would understandably be how their risk model performed during 2008, a highly volatile period which was driven by the "worst financial crisis since the Great Depression" according to Gary Becker (CITE), a Nobel-prize winning Economist. Interestingly, the forecast for Amazon was fairly accurate whereas the forecast for PG was not. One reason for this could be the fact that a stock like Amazon was highly volatile during the training sample, which included data from previous years (HOW MANY?), but PG was fairly calm. How would it be possible for a univariate model such as CAViaR, that does not explictly account for other factors, to forecast well? What if a volatile stock such as AMZN was included into the forecast for PG - would it improve the forecast?

Thus, the idea of combining stocks into a multivariate setting to capture correlations and better forecast risk was formed. A natural choice appeared to be the diffusion index model, originally developed by Stock and Watson for predicting conditional means [TWO CITATIONS]. The model for forecasting the conditional mean is specified below.

Diffusion Index Model

A useful means of predicting stock movements in the future is the Stock and Watson diffusion index. The model is outlined below, which is adapted from Multivariate Time Series Analysis With R and Financial Applications by Ruey S. Tsay [ADD CITATION].

There are two relevant equations:

$$z_t = L f_t + \epsilon_t$$

and

$$y_{t+h} = \beta' f_t + e_{t+h}$$

In the first equation $z_t = (z_{1t},, z_{kt})'$ is an observed time series with mean 0, f_t is an m-dimensional vector of common factors with mean 0 and identity covariance matrix, L is a $k \times m$ loading matrix, and ϵ_t is a i.i.d. sequence of random vectors with mean 0 and covariance matrix Σ_e .

In the second equation, which represents the h-step ahead prediction based on f_t , y_t is the scalar time series of interest, h is the forecast horizon, β represents the vector of coefficients, and e_t is a sequence of uncorrelated random variables with mean 0 and constant variance.

To model the data, principal component analysis is performed on the covariates described below to obtain an estimate of f_t . Then the β coefficients are estimated using ordinary least squares.

CAViaR Model

However, work needed to be done to align the diffusion index model with the CAViaR model, which is defined below. The following variables are required for use in the CAViaR model:

A vector of portfolio returns

Adaptive CAViaR Model

$$f_t(\beta_1) = f_{t-1}(\beta_1) + \beta_1 \left[\left(1 + \exp(G[y_{t-1} - f_{t-1}(\beta_1)]) \right)^{-1} - \theta \right]$$

Symmetric Absolute Value CAViaR Model

$$f_t(\beta) = \beta_1 + \beta_2 f_{t-1}(\beta) + \beta_3 |y_{t-1}|$$

Asymmetric Slope CAViaR Model

$$f_t(\boldsymbol{\beta}) = \beta_1 + \beta_2 f_{t-1}(\boldsymbol{\beta}) + \beta_3 (y_{t-1})^+ + \beta_4 (y_{t-1})^-$$

Indirect GARCH (1,1) CAViaR Model

$$f_t(\boldsymbol{\beta}) = (\beta_1 + \beta_2 f_{t-1}^2(\boldsymbol{\beta}) + \beta_3 y_{t-1}^2)^{1/2}$$

[ADD SPECIFICATION]

As such, the following model is used to combine the two ideas:

VAR = INTERCEPT + PAST VALUES + AR COMPONENT + ERROR

Data Used

The response variable used in this analysis is SPY, which is an exchange-traded fund that aims to track the performance of the S&P 500, which is discussed above. It is broadly used as a bellweather of the U.S. economy (CITE), and has the advantage of avoiding survivorship bias - while an individual stock might go bankrupt or merge with another, it's reasonable to assume that these issues do not apply with an ETF.

Following this logic, there are several classes of response variables used in this analysis. The first group is a set of U.S. sector ETFs obtained from Seeking Alpha using the link below. As with the response variable, these ETFs were publicly traded throughout the Great Recession.

https://seekingalpha.com/etfs-and-funds/etf-tables/sectors

- a. Utilities (XLU)
- b. Consumer Staples (XLP)
- c. Healthcare (XLV)
- d. Technology (XLK)
- e. Consumer Discretionary (XLY)
- f. Industrial (XLI)
- g. Financial Services (XLF)
- h. Basic Materials (XLB)
- i. Energy (XLE)

The second is Global Sector ETFs, also obtained from Seeking Alpha. The rationale for including these is that perhaps some global exposure is useful in understanding the broader market.

- a. Utilities (JXI)
- b. Consumer Staples (KXI)
- c. Healthcare (IXJ)
- d. Telecommunications (IXP)
- e. Technology (IXN)
- f. Consumer Discretionary (RXI)
- g. Industrial (EXI)
- h. Financial Services (IXG)
- i. Basic Materials (MXI)
- j. Energy (IXC)

The third is bond ETFs, also obtained from [CITE]. Like the previous two, these ETFs potentially contain forward-looking information about the stock market. Link below:

- a. iShares 1-3 Year Treasury Bond Fund (SHY)
- b. iShares 7-10 Year Treasury Bond Fund (IEF)
- c. iShares 20+ Year Treasury Bond Fund (TLT)
- d. iShares iBoxx \$ Investment Grade Corporate Bond ETF (LQD)

Lastly, all of the above are run together.

Conclusions and Future Work

The problem of how to predict a low quantile of a stock's log return when the training sample is substantially different than the test scenario is an enormously difficult problem. Almost axiomatically, the distribution is nonstationary over time. How is it possible to predict the return of an index like the S&P500 during a period of market turmoil such as the great recession? While the CAViaR model performs comparatively well during times of stress, it performs about the same as the multivariate model during more benign economic periods.

This conclusion drawn from the above results might support the notion of combining the two models in some

sort of a mixture model - aiming to use the basket of ETFs during good times, and use the CAViaR ARMA specification during bad times. The approach of using ETFs allows a prediction based on forward-looking expectations of fundamental factors. Indeed, ETFs are just baskets of individual stocks or bonds, and those securities are (in theory) based on rational expectations about future resources, market conditions, etc - the microfoundations of what drives our economy. The ARMA specification, while practically and statistically sound, is contradicted by economic theory and practice - the weak form of the efficient market hypothesis states that it is impossible to forecast future values of asset prices using past values. But perhaps this view is incomplete.

Any model that attempts to capture relationships in the real world will only work until an omitted variable is found. The elegance of the multivariate CAViaR model is that it provides insight into why a prediction is wrong; the change in the angle between resultant vectors is a sensible measurement of economic changepoints (CHANGE). However, errors in the world are costly, and it's wishful thinking to say that explaining why the error occurred is sufficient.

As such, for future work it's worth exploring the notion of weighting an ARMA-approach more heavily when predictions using fundamentals were too high, then not only would this after-the-fact recognition be achieves, but also a hierarchical model that captures fundamental relationships in the economy and potentially changes our understanding of asset prices in general - a synthesis between Keynes' animal spirits during a time of severe crisis; where a model cannot explain shifts, and a more rational world that explains other periods. In addition to significant predictive power because of the switching between the two worlds, there's also an elegant explanation; a way to explain changes in the usefulness of the underpinnings in the economy. Because of the flexibility of the model, it's entirely possible that a whole gamut of variables could be tossed in and backtested to when "changepoints" occurred.

Additional future work involves developing theoretical guarantees on the parameters in the multivariate CAViaR model. One advantage of both the diffusion index model and the CAViaR model is that both have theorems about asymptotic normality and consistency [CONFIRM].
